ABSTRACT

Bovine *Streptococcus* are one of the main pathogens causing bacterial disease such as mastitis and endometritis in dairy farming. The virulence factors produced by *Streptococcus* are related to the occurrence of inflammation. To investigate the correlation between antimicrobial resistance and virulence traits of bovine *Streptococcus* isolates. Induced resistance was conducted for *Streptococcus pneumoniae* ATCC49619 and erythromycin-sensitive strains by gradually increasing the antimicrobial concentration. Plasmid conjugation test was carried out by membrane filtration method. The correlation between antimicrobial resistance and virulence traits was analyzed by LD₅₀ and related genes. Sensitive *Streptococcus* isolates to erythromycin and *S. pneumoniae* ATCC49619 were induced to resistance *in vitro*, MIC value was from ≤ 0.5 $\mu\text{g/mL}$ up to ≥ 64 $\mu\text{g/mL}$, and *ermB* or *mefA* resistant gene were carried. Transfer rate of resistance was 100% by plasmid conjugant, conjugants had obtained the resistance phenotype and the related resistance genes from the donor bacteria. The LD₅₀ of conjugants and induced resistance strains compared with parental strain, the virulence was lower than sensitive strains. The present study demonstrated that the virulence of resistant *Streptococcus* strains obtained by different drug resistance transfer methods was lower than that of their parents.

INTRODUCTION

Streptococcus belongs to a gram-positive bacterium, which is widely distributed in cow skin, bedding, feces and urine, sewage and other environments. The pathogenic strain can cause cow infection through contact transmission, such as mastitis and endometritis (Wu *et al.*, 2019). Additionally, during recent decades, livestock production (including the dairy production) has tended to a high-density and intensive production model, leading to frequent occurrence of animal diseases, and antibiotics are therefore widely used in feed and veterinary clinical practice to prevent and treat animal bacterial infectious diseases (Guo *et al.*, 2020; Liu *et al.*, 2020), while the rapid emergence

and dissemination of resistance has become a major concern of public health security (Liu *et al.*, 2019; Wu *et al.*, 2019), and it also includes the issue of drug resistance in *Streptococcus*. Besides, in addition to public health issues, drug resistance makes the veterinary clinical treatment of *Streptococcus* extremely difficult and seriously affect the healthy production of dairy cows (Ding *et al.*, 2016).

The mechanism of bacterial drug resistance has become an important and extensive research topic in clinical microbiology (Martínez *et al.*, 2002). Previous studies have found that the major determinants of the resistant mechanism are derived from horizontal gene transfer in other organisms, and common essential characteristics have also been reported in studies of pathogen virulence. On the other hand, it has been shown that antibiotic resistance genes and virulence genes can be in the same mobile components, such as plasmids, transposons, phages, integrons, and gene clusters (Villa *et al.*, 2005; Reid *et al.*, 2019). Johnson *et al.* (2005) reported that resistance and virulence genes are located on the same or different plasmids, and both can be transferred simultaneously with plasmid. It was suggested that the plasmid pAPEC-O1-R and ColBM which mediates

resistance and virulence, respectively, could co-transfer through the conjugation in avian pathogenic *Escherichia coli* (Johnson *et al.*, 2006). The pCERC3 plasmid was also found to be both virulence and resistance plasmid in *E. coli* (Moran *et al.*, 2016). Further studies have shown a correlation between virulence and antibiotics (Rathnayake *et al.*, 2012). Ghorbel *et al.* (2019) observed a significant correlation between the virulence pattern and the map of antimicrobial agents. Azzam *et al.* (2017) showed that multiple antibiotics resistances was strongly correlated with bacterial virulence in wastewater ecosystems. Vila *et al.* (2002) reported that when bacteria acquired antibiotic resistance, their virulence decreased, the study of the mechanism showed that most strains increase resistance by changing their own expression or protein structure (Wang *et al.*, 2016).

At present, most studies on its correlation are focused on human medicine and ecological environment, while few studies on bovine *Streptococcus*. Hence, the present study was conducted to investigate the correlation between antimicrobial resistance and virulence traits of bovine *Streptococcal* isolates by using *in vitro*-induced drug resistance and resistant plasmid conjugation of sensitive *Streptococcal* isolates, which will render rationale basement for controlling bacterial disease caused by *Streptococcal* infection.

MATERIALS AND METHODS

Tested strains

S. pneumoniae ATCC49619 was provided by laboratory. Bovine *Streptococcal* isolates which sensitive to erythromycin (MIC < 1 µg/mL) and the donor bacteria

both came from clinical cases. *Streptococcus dysgalactiae* CVCC3701 and *Streptococcus dysgalactiae* CVCC3701-PEN (penicillin-induced resistance) were provided by other researchers in this study.

In vitro induced resistance test

The preserved standard strain (ATCC49619) and 15 erythromycin-sensitive *Streptococcal* isolates were inoculated into the BHI broth with serum, and incubated at 37°C for 6 h. A small amount of bacterial solution was picked to mark on M-H agar plates and incubated at 37°C for 16-20 h. BHI broth containing the sub inhibitory concentration of antibiotic was prepared and passed at 37°C. Meanwhile, the negative control of broth was made and transferred every 3 days. The concentration of the induced antibiotic was gradually increased by 2 times until the MIC of the test strain rose to the resistance range (Gautier *et al.*, 2002). The stability of resistant progeny was tested, and related resistant genes (*ermB*, *mefA*) were detected by PCR. Primer information was shown in Table I.

Plasmid conjugation test

The test was performed by membrane filtration method (Werner *et al.*, 2003). 20 *Streptococcal* isolates that were both resistant to tetracycline and sensitive to erythromycin were selected as the donor bacteria, and *S. pneumoniae* ATCC49619-ERY (erythromycin-induced resistance) was used as the recipient bacteria. The suitable antibiotic concentrations of erythromycin and tetracycline were screened, respectively. The tested strains were inoculated into the BHI broth with serum and incubated at 37°C for 18 h aerobically in 5% CO₂. That was adjusted to 10⁸ CFU/mL. The 5 µL bacteria solution was absorbed

into 1 mL liquid medium for 4 h by shaking culture. The donor and recipient were mixed at 1:3 (20 μ L, 60 μ L) and coated on the sterile filter membrane. The filter membrane was placed in the BHI agar plates at 37°C for 18-24 h, after that was washed with 1 mL BHI broth and transplanted into BHI agar plates containing a certain concentration of erythromycin and tetracycline. The results were observed after 36-48 h. Single colony was selected and inoculated into LB broth at 37°C for the identification of conjugants.

Conjugant identification

MIC and multiple PCR were used to identify the

conjugants (Huys *et al.*, 2004). MIC was detected by double dilution method.

Detection of virulence on bovine *Streptococcus*

LD₅₀ assay was performed on strains with resistant phenotypes, resistant and virulence genes (*bac*, *bca*, *scpB*, *LMB*, *cyl*, *glnA*, *CFB*, *hylB*) after induction and plasmid conjugation. Half of the lethal dose (LD₅₀) was determined by Bliss (1936) method. The experimental design was divided into a blank control group and six experimental groups. Three dilution degrees were set in equal ratio between the LD₀ and LD₁₀₀, with a total of 5 gradients in the

experimental group. After inoculation, the symptoms, time of death and the number of deaths were recorded.

RESULTS

Erythromycin-sensitive strain induced resistance

MIC values of all strains after erythromycin induction were shown in Table II. The results showed that 15 clinical isolates and *S.pneumoniae* ATCC49619 developed high resistance after induction for more than 10 generations ($\text{MIC} \geq 64 \mu\text{g/mL}$). MIC value of *S.pneumoniae* ATCC49619 reached $256 \mu\text{g/mL}$. Only 3 *S. agalactiae* had been $64 \mu\text{g/mL}$ after induction, and other isolates had $\text{MIC} \geq 128 \mu\text{g/mL}$. The MIC value of resistant offspring was not changed after culturing in a drug-free medium for 5 generations. The resistance was stable.

Antimicrobial resistance genes

Resistant genes were detected by PCR after inducing. 15 strains amplified a fragment of 442bp (*ermB*), and 1 strain amplified a fragment of 346bp (*mefA*). Partial test results were shown in Figure 1.

Plasmid conjugation test

Plasmid conjugation was performed between 20 donor and the recipient bacteria (ATCC49619-ERY), respectively. Conjugation and parent strains were also tested for their susceptibility to 11 antimicrobial agents and the results are shown in Table III. The MIC value of

the recipient bacteria against erythromycin was $256 \mu\text{g/mL}$. At least 50% of the donor bacteria showed resistance to tetracycline (MIC_{50} value = $64 \mu\text{g/mL}$ and MIC_{90} value = $128 \mu\text{g/mL}$). The MIC_{50} and MIC_{90} values of conjugation against erythromycin were greater than $256 \mu\text{g/mL}$, MIC_{50} to tetracycline was $64 \mu\text{g/mL}$, and MIC_{90} was $128 \mu\text{g/mL}$ after plasmid conjugation test. In addition, the resistant phenotypes of β -lactams, quinolones, amides and vancomycin did not transfer to the conjugation, while the resistant phenotypes of lincomines in the donor bacteria were more consistent with conjugation.

Identification of conjugons

The DNA of conjugation was extracted and multiplex PCR was performed. Partial electrophoresis results are shown in Figure 2. The results showed that the tetracycline resistance genes *tetM* (740bp) and *tetL* (993bp) be detected in the donor bacteria with high tetracycline resistance, *ermB* (442bp) be detected in the recipient bacteria with high erythromycin resistance, and both tetracycline and erythromycin resistance genes be detected in the conjugation.

Virulence of Streptococcus

LD₅₀ was performed on 5 strains of induced resistance and plasmid conjugation. The genes of resistance and virulence are shown in Table IV. According to the preliminary experimental results, the LD₀ and LD₁₀₀ of all the tested strains are shown in Table V, and the LD₅₀ results are shown in Table VI. The LD₅₀ of donor bacteria (name: WR38), recipient bacteria (name: ATCC49619-ERY) and conjugation (name: PC12) from plasmid conjugation transfer test were analyzed by Bliss method, the results showed that the virulence of conjugation PC12 was decreased compared with that of the recipient ATCC49619-ERY, and its LD₅₀ was increased by 1.6 times compared with that of the recipient.

The results of CVCC3701 and CVCC3701-PEN of *S. dysgalactiae* from the induced resistance test showed

that the LD₅₀ value of the strain was significantly different before and after induction, and the LD₅₀ of the strain after induction was increased by 1.1×10² times compared with that before, indicating that the virulence of the strain after induction decreased significantly.

Table VI.- The LD₅₀ of tested strains on the mouse. A dose (0.5 mL) of vaccine was administered to 8 mice i.p. for each experimental group.

DISCUSSION

Erythromycin-sensitive Streptococcus induced resistance

Streptococcus as the main pathogens that cause a variety of suppurative inflammation in animals and humans, such as mastitis, endometritis, sepsis and neonatal sepsis, meningitis. Macrolides are a class of antibiotics

used in the treatment of gram-positive bacterial infections. Some of them are also added into the feed, resulting in the gradual increase of resistance.

At present, the resistance rate of *S. agalactiae* to erythromycin in mastitis was as high as 94.1% from some parts of China, while India was 33.3% (Jain *et al.*, 2012). Previous studies also found that the resistance rate of group B *Streptococcus* against erythromycin was also increasing by years in Canada and Taiwan (Sherman *et al.*, 2012; Ko *et al.*, 2001; Helena *et al.*, 1997). The resistance rate of *Streptococcus suis* to macrolides was more than 50% (Martel *et al.*, 2001). In Asia, such as China, Vietnam and Korea, clinical isolates of *S. pneumoniae* had resistance rates of over 70% to macrolides (Song *et al.*, 2004; Sahm *et al.*, 2008). Erythromycin resistance model was successfully established by induction *in vitro*, and the adaptability of *Streptococcus* was proved to be different due to antibiotic differences in the experiment. *ErmB* gene was detected in most resistant *Streptococcus* in the test, suggesting that erythromycin resistance methylase may be the major mechanism of resistance in the present study. The results suggest that low doses and concentrations of drugs will not kill bacteria, but it will adapt to the environment by producing the corresponding resistance genes or genetic mutations to escape clinically. The standard strain ATCC49619-ERY of *S. pneumoniae* resistant only to erythromycin was obtained through the model, and the changes in virulence characteristics of the same strain before and after induction of resistance could be more directly compared, which provided a single resistant strain for subsequent plasmid conjugating tests.

Plasmid conjugation test of bovine *Streptococcus*

Bacterial resistance includes intrinsic and acquired resistance. Studies have shown that many resistant genes are located on mobile DNA components such as plasmids, transposons and integrons, and can also be transmitted between bacteria by conjugation plasmids, transposons, integrons and phages (Zhao *et al.*, 2011). The acquisition of resistant plasmids is the most common mechanism of bacterial resistance (Bruinsma *et al.*, 2004), conjugation is the primary mode of transmission of resistant genes in bacteria (Brown *et al.*, 1999).

In this study, a high tetracycline-resistant *Streptococcal* plasmid conjugation and transfer test was carried out by membrane grafting method. The resistance of tetracycline and related resistance genes (*tetM* and *tetL*) were successfully transferred into the recipient bacteria by 20 strains of highly tetracycline resistant donor. More than 80% of the colonies growing in the two antibiotics screening plate acquired the properties of the donor and recipient bacteria, while the remaining colonies only

acquired the resistance phenotype of tetracycline but did not detect genes. The two antibiotics concentration was selected for screening to determine the conjugation and distinguish from donor and recipient bacteria.

The resistance to tetracycline is mainly acquired through the resistance gene transferring in conjugation plasmids, and the *tetL* gene encodes efflux pump protein which often exists in small plasmids with transmissibility. *TetM* gene encodes ribosomal protective proteins which mainly located in transposons of the Tn916-Tn1545 family (Huys *et al.*, 2004). The family forms a ring structure, which can transfer intracellular and intercellular. Tn916 has a wide host range and can transfer the *tetM* gene to gram-negative bacteria and even to mycoplasma (Lancaster *et al.*, 2004), which may be the reason why tetracycline is susceptible to transfer to others. It is worth noting that the MIC of clindamycin in conjugation is improved compared with the recipient bacteria. Lincomines can be methylated by ribosomes, and produced cross-resistant with macrolidenes. The macrolidene resistance gene *ermB* is usually located in Tn1545 and Tn917 (Okitsu *et al.*, 2005), suggesting that the transfer of resistance of lincomines may be related to transposon Tn1545.

LD₅₀ of bovine *Streptococcus* before and after resistance

In order to demonstrate the changes in resistance and virulence characteristics of *Streptococcus*, we used plasmid conjugation and *in vitro* induced resistance tests to gradually transform the sensitive into resistant *Streptococcus* with clear background to demonstrate the changes of the same strain in the process of resistance. The results showed that the LD₅₀ value of the induced strain CVCC3701-PEN increased by 1.1×10^2 times compared with that of the parent strain before induction. the LD₅₀ value of conjugation increased by 1.6 times compared with that of the recipient bacteria, indicating that the virulence of the sensitive bacteria decreased after acquiring resistance. Some researchers had found that virulence and resistance genes can be transmitted and transformed to a certain extent (Alexander *et al.*, 2011; Barton, 2000), antibiotic resistance also existed in genes that encode bacteriocins (Chelliah *et al.*, 2019), iron carriers (Zhang *et al.*, 2017), cytotoxins (Carlson *et al.*, 2001), and adhesion factors (Laporta *et al.*, 1986).

Pathogenicity islands (PAI) is a special genomic island that contains multiple virulence genes as well as plasmids, transposons and integrons. PAI constructed a new genomic island by horizontal transfer of virulence genes through plasmids or transposons, thereby expanding the bacterial spectrum of the virulence island. However, PAI was often associated with a tRNA gene or insertion sequence, and present in strong strains generally, but rarely distributed

in the associated weak or no strains (Zhu *et al.*, 2013). It is suggested that the donor bacteria may not exist a PAI due to its weak virulence ($LD_{50} = 1.13 \times 10^8$ CFU/mL), and virulence factors are difficult to transfer horizontally.

It has demonstrated that penicillin-resistant *S. pneumoniae* may be less virulent than sensitive strains (Azoulay *et al.*, 2000), multiple drug resistance leading to reduced virulence (Lehtolainen *et al.*, 2003). Resistance to rifampicin led to a decrease in virulence (Neill *et al.*, 2006). The expression of virulence genes was decreased in fluoroquinolone-resistant strains (Schaeffer, 2002; Liu *et al.*, 2009). In this regard, many scholars put forward the concept of biological adaptability cost, the decrease of fitness caused by resistance mutation (Andersson, 2006). Therefore, abnormal bacterial regulation may occur when movable elements are engaged, and that is the increased cost of adaptation. Björkman *et al.* (1998) reported that resistant *Salmonella typhimurium* was less virulent to mice due to mutations in *rpsL*, *rpoB* and *gyrA* genes, but it quickly repaired its adaptability and virulence by compensating mutations. It is suggested that the toxicity of resistant bacteria decreased, while a variety of virulence genes were detected after induction of resistance, which may be caused by the fact that *S. dysgalactiae* CVCC3701-PEN stimulated compensatory adaptation, that needs to be further verified.

CONCLUSION

To summarize, based on the findings of the above three experiments, this study applied the standard strain of *S. pneumoniae* and *S. dysgalactiae*, and obtained different resistant strains with different drug resistance transfer methods, the results that the virulence of the resistant strain decreased compared with the parent strain, so that the results were mutually supported and verified.
